Abstract. We implemented a quasi time-dependent 2D stochastic model of solar modulation describing the transport of cosmic rays (CR) in the heliosphere. Our code can modulate the Local Interstellar Spectrum (LIS) of a generic charged particle (light cosmic ions and electrons), calculating the spectrum at 1AU. Several measurements of CR antiparticles have been performed. Here we focused our attention on the CR antiproton component and the antiproton over proton ratio. We show that our model, using the same helispheric parameters for both particles, fit the observed ratio. We show a good agreement with BESS-97 and PAMELA data and make a prediction for the AMS-02 experiment.

1 Introduction

Galactic cosmic rays (GCRs) are nuclei, with a small component of leptons, mainly produced by supernova remnants [Blasi (2010)], confined by the galactic magnetic field to form an isotropic flux inside the galaxy. Before reaching the Earth orbit they enter the heliosphere, the region where the interplanetary magnetic field is carried out by the solar wind (SW). In this environment they undergo diffusion, convection, magnetic drift and adiabatic energy loss, resulting in a reduction of particles flux at low energy (<1-10 GeV) depending on solar activity and polarity. This effect is known as solar modulation. We have developed a 2D (radius and heliocolatitude) model of GCR propagation [Bobik et al. (2003)] in the heliosphere, by using stochastic differential equations (SDEs). The model depends on measured values of the SW velocity on the ecliptic plane (\(V_0\)), tilt angle (\(\alpha\)) of the neutral sheet and estimated values of the diffusion parameter (\(k_0\)); details on parameters are discussed in section 2 and 3. This model includes drift transport due to magnetic field curvature and gradients, as well the presence of a tilted neutral sheet describing properly periods of low and medium solar activity. Modulated fluxes depend on solar activity but also on particle charge and solar magnetic polarity [Boella et al. (2001)].

2 Stochastic 2D Monte Carlo code

The GCR transport in the Heliosphere is described by a Fokker-Planck equation, the so-called Parker equation [Parker (1965)]:

\[
\frac{\partial U}{\partial t} = \frac{\partial}{\partial x_i} \left(K_{S} \frac{\partial U}{\partial x_j} \right) - \frac{\partial}{\partial x_i} (V_{SW} U) + \frac{1}{3} \frac{\partial V_{SW}}{\partial T} (\rho T U) - \frac{\partial}{\partial x_i} (v_{D_i} U)
\]

(1)

where \(U\) is the cosmic ray number density per unit interval of particle kinetic energy, \(t\) is the time, \(T\) is the kinetic energy (per nucleon), \(V_{SW}\) the SW velocity along the axis \(x_i\), \(v_{D_i}\) is the drift velocity related to the antisymmetric part of diffusion tensor [Jokipii and Levy (1977)], \(K_{ij}\) is the symmetric part of the diffusion tensor and \(\rho = (T + 2T_0)/(T + T_0)\) [Gleeson et al. (1967)], where \(T_0\) is particle’s rest energy. This partial differential equation is equivalent to a set of ordinary SDEs that can be integrated with Monte Carlo (MC) techniques. The integration time step (\(\Delta t\)), is taken to be proportional to \(r^2\) (\(r\) is the distance from the Sun) avoiding oversampling in the outer heliosphere and therefore saving CPU time [Alanko-Huotari et al. (2007)]. We considered the 2D (radius and colatitude) approximation of Eq. [1] and from this we calculate the equivalent set of SDEs:

\[
\Delta r = \frac{1}{r^2} \frac{\partial (r^2 K_{rr})}{\partial r} \Delta t + (V_{SW} + v_{Dr} + v_{DNS}) \Delta t + R_q \sqrt{2K_{rr} \Delta t}
\]

(2)
\[ \Delta \mu = \frac{1}{r^2} \frac{\partial}{\partial \mu} \left[ (1 - \mu^2) \frac{K_{\theta \theta}}{\partial \mu} \right] \Delta t - \left( \frac{\sqrt{1 - \mu^2}}{r} v_{D_p} \right) \Delta t + R_g \sqrt{2 K_{\theta \theta} (1 - \mu^2)} \Delta t \]

\[ \Delta T = - \left( \frac{2 \partial v_{sw}}{3} \right) \Delta t \]  

where \( \mu = \cos \theta \), with \( \theta \) colatitude, and \( R_g \) is a gaussian distributed random number with unitary variance. Here the drift velocity is split in regular drift (radial drift \( v_{D_r} \), latitudinal drift \( v_{D_\phi} \)) and neutral sheet drift (\( v_{D_{NS}} \)) as described by Hattingh and Burger (1995). The radial diffusion coefficient is \( K_{rr} = K_{\theta \theta} \cos^2 \psi + K_{\perp \perp} \sin^2 \psi \) [Potgieter et al. (1993)], where \( \psi \) is the angle between radial versor and direction of the solar magnetic field described below. The latitudinal coefficient is \( K_{\theta \theta} = K_{\perp \perp} \) [e.g., see Potgieter and Le Roux (1994)]. We note as the perpendicular diffusion coefficient has two components, one in the radial direction (\( K_{\perp r} \)) and one in the polar direction (\( K_{\perp \theta} \)) as shown in Potgieter (2000). We define \( (K_{\perp})_0 \) as the ratio between perpendicular and parallel diffusion coefficients, therefore \( K_{\perp} = (K_{\perp})_0 K_{\parallel} \). We fixed this value: \( (K_{\perp})_0 = 0.05 \) while \( (K_{\parallel})_0 = f(\theta)(K_{\perp})_0 \), (where \( f(\theta) = 10 \) close to the poles and \( f(\theta) = 1 \) in the equatorial region). Potgieter (2000), to reproduce the correct magnitude and rigidity dependence of the latitudinal cosmic ray proton and electron gradients [cf. Potgieter et al. (1997), Burger et al. (2000)]. The parallel diffusion coefficient is \( K_{\parallel} = k_0 P / (B_{\parallel} / 3B) \) [Potgieter and Le Roux (1994)]; here \( k_0 \approx 0.05 - 0.3 \times 10^{-3} \) \( \text{AU}^2 \text{G}^{-1} \text{s}^{-1} \), is a diffusion parameter depending on the solar activity (see section 3). \( \beta \) is the particle velocity, \( P \) is the CR particle’s rigidity, \( K_P = P \), \( B_{\parallel} \) is the value of heliospheric magnetic field at the Earth orbit, and \( B \) is the magnitude of the Heliospheric Magnetic Field (HMF) [Hattingh and Burger (1995)]:

\[ B = \frac{A}{r^2} (e_r - \Gamma e_\phi) [1 - 2H(\theta - \theta')] \]  

where \( A \) is a coefficient that determines the field polarity and allows \( |B| \) to be equal to \( B_{\parallel} \), i.e., the value of IMF at the Earth orbit; \( \theta' \) is the polar angle determining the position of the heliospheric current sheet (HCS) [Jokipii and Thomas (1981)]; \( H \) is the Heaviside function, thus \( [1 - 2H(\theta - \theta')] \) for the change of sign between the two regions - above and below the HCS - of the heliosphere; finally \( \Gamma = \tan \psi \approx \omega \sin \theta \), with \( \psi \) the spiral angle. The Parker field has been modified introducing a small latitudinal component \( B_\theta = \frac{A}{r^2} (r / r_0) \delta(\theta) \) with \( \delta(\theta) = 8.7 \times 10^{-5} / \sin \theta \), thus allowing one to obtain \( \nabla \cdot B = 0 \) and a field magnitude according to Jokipii and K\'ota (1989):

\[ B = \frac{A}{r^2} \sqrt{1 + \Gamma^2 + \left( \frac{r}{r_0} \right)^2 \delta^2} \]  

Fig. 1. \( k_0 \) values versus monthly SSN. The linear fit is also shown. Reported values cover the time period 1951-2004.

Values of the tilt angle \( \alpha \) are computed using two different models, described in Hoeksema (1995), fitting separately periods of increasing solar activity and periods of decreasing solar activity [Ferreira and Potgieter (2004)]. The three drift components do not depend on external parameters, except the solar polarity, so \( \alpha > 0 \) for positive periods and \( \alpha < 0 \) that increases the magnitude of the HMF in the polar regions without a modification of the field topology. This component produces a lower magnetic drift velocity in this region, with the effect of a lower CR penetration along polar field lines in the inner part of the heliosphere [Jokipii and K\'ota (1989)].

We use a SW broad smoothed profile according to Ulysses data for periods of low solar activity [McComas et al. (2000)], described by the relation \( V_{sw}(\theta) = V_{max} \) if \( \theta < 30^\circ \) or \( \theta > 150^\circ \) and \( V_{sw}(\theta) = V_0 \cdot (1 + |\cos \theta|) \) if \( 30^\circ < \theta < 150^\circ \) where \( V_0 \) is approximately 400 km/s and \( V_{max} \) is 760 km/s. Drift effects are included through analytical effective drift velocities: in the Parker spiral field we evaluated drift due to gradient, curvature and neutral sheet that modify the integration path inside the heliosphere. We adopted the approach of Potgieter and Moraal [Potgieter and Moraal (1983)], because it is able to reproduce the effects of drift in both quiet and active solar periods [a discussion on other models can be found in Bobik et al. (2010)]. In this model the drift coefficient is modified with a transition function that simulates the effect of a wavy neutral sheet. The sharpness of this function is related to \( \alpha \) angle, expanding or shrinking the region of influence of neutral sheet drift. As LIS, both for protons and antiprotons, we use the ones used in Casaus (2009) and obtained from Galprop [1].

3 Parameters and Data Sets
for negative periods [Bobik et al. (2003)]. We selected CR p and \( \bar{p} \) data from several experiments in order to compare and tune model results. We modulated separately p and \( \bar{p} \) LIS spectra and then we computed the ratio. In this paper we show experimental data taken during periods of low solar activity: the comparison with BESS-97 (A>0 July 1997, see Orito et al. (2000)) and PAMELA (A<0 from 2007 to 2008, see Adriani et al. (2010)). \( V_0 \) and \( B_0 \) values for these periods were obtained from NSSDC OMNIWeb system[5] by 27 daily averages, while tilt angle values from the Wilcox Solar Laboratory [Hoeksema (1995)]. We estimated the values of \( k_0 \), needed to evaluate the CR modulation in different conditions, from the modulation parameter reported in Usoskin et al (2005). We searched a relation between the estimated \( k_0 \) values and the monthly Smoothed Sunspot Numbers (SSN). We found that there is a nearly linear relation between \( k_0 \) and SSN[3] values (see Fig. 1), with a Gaussian distribution of the best fit with a RMS of 19%. This is a first crude estimation, we will perform a more complex analysis, e.g. fitting separately different solar phases, in order to avoid systematics in the relation and to reduce the RMS. In this way we can use the estimated SSN values to obtain the diffusion coefficient \( k_0 \). Following this approach we introduced in our code a gaussian random variation of \( k_0 \) with a RMS of 19%. Results of the simulation with and without the gaussian variation are consistent inside the indetermination of the code (around 5%). Our code simulates a diffusive propagation of a CR entering the heliosphere from its outer limit, that we located at 100 AU (note that in Decker et al. (2005) the Termination Shock is located at 94 AU), and reaching the Earth at 1 AU; the effects of heliosheath and termination shock are not taken into account in the present model. We evaluated the time \( t_{sw} \) needed by the SW to expand from the outer corona up to 100 AU, with a minimum speed of \(~400 \) km/s it takes nearly 14 months, while the time interval \( \tau_{ev} \) of the stochastic evolution of a quasi particle inside the heliosphere from 100 AU down to 1 AU is between 1 month (at 200MeV) and few days (at 10 GeV). This scenario, where \( \tau_{ev} < t_{sw} \) and \( t_{sw} >> 1 \) month, indicates that we should use different parameters (monthly averages) to describe the conditions of heliosphere in the modulation process. In fact at 100 AU, where particles are injected, the conditions of the solar activity are similar to those present at the Earth 14 months before. Therefore, we can divide the heliosphere in 14 regions as a function of the radius. For each region we evaluated \( k_0, \alpha \) and \( V_{sw} \), in relation to the time spent by the solar wind to reach this region. We indicate the present treatment accounting for the time evolution of the solar parameters as a dynamic approach of the heliosphere.

4 Results

Results obtained with our propagation code are shown in Figs. 2 and 3. Simulated fluxes obtained using parameters dependent on the heliospheric region agree with measured data within the experimental error bars. This happens both in periods with A>0 (BESS-97), and in periods with A<0 (PAMELA). This means that current treatment of the Heliosphere improves the understanding of the complex processes occurring inside the Solar Cavity. Our code can be

![Fig. 2. Comparison of simulated \( \frac{\bar{p}}{p} \) ratio at 1 AU and experimental data: BESS (1997).](http://omniweb.gsfc.nasa.gov/form/dx1.html)

![Fig. 3. Comparison of simulated \( \frac{\bar{p}}{p} \) ratio at 1 AU and experimental data: PAMELA (2007-2008).](http://www.sidc.oma.be/sunspot-data/)
AMS-02 mission that will be installed on the ISS in 2011: we choose January 2012. For this period we show in Fig. 4 the predictions of GCR modulation for the $\bar{p}/p$ ratio. In order to reduce the uncertainty it is important to compare our model with the AMS-02 data because of the huge statistics and the long time covered.

5 Conclusions

We developed a 2D stochastic MC code for particles propagation across the heliosphere. We compared the ratios of $\bar{p}/p$ fluxes measured by BESS and PAMELA with those obtained from the present MC code. In the present calculations we used - for the parameters $k_0$, $\alpha$ and $V_{sw}$ - values corresponding to the periods of data taking. This description of the heliosphere and the forward approach seem to properly account for the propagation of GCR in the solar cavity. Recent measurements [Adriani et al. (2010)] have pointed out the needs to reach a high level of accuracy in the modulation of the fluxes, in relation to the charge sign of the particles and the solar field polarity. This aspect will be even more crucial in the next generation of experiments like AMS-02.
